ABSTRACT

We investigated the pharmacology of three novel compounds, Org 27569 (5-chloro-3-ethyl-1*H*-indole-2-carboxylic acid [2-(4-piperidin-1-yl-phenyl)-ethyl]-amide), Org 27759 (3-ethyl-5-fluoro-1*H*-indole-2-carboxylic acid [2-(94-dimethylamino-phenyl)-ethyl]-amide), and Org 29647 (5-chloro-3-ethyl-1*H*-indole-2-carboxylic acid (1-benzyl-pyrrolidin-3-yl)-amide, 2-enedioic acid salt), at the cannabinoid CB₁ receptor. In equilibrium binding assays, the Org compounds significantly increased the binding of the CB₁ receptor agonist [³H]CP 55,940 [(1*R*,3*R*,4*R*)-3-[2-hydroxy-4-(1,1-dimethylheptyl)phenyl]-4-(3-hydroxypropyl)cyclohexan-1-ol], indicative of a positively cooperative allosteric effect. The same compounds caused a significant, but incomplete, decrease in the specific binding of the CB₁ receptor inverse agonist [³H]SR 141716A [*N*-(piperidin-1-yl)-5-(4-chlorophenyl)-1-(2,4-dichlorophenyl)-4-methyl-1*H*-pyrazole-3-carboximide hydrochloride], indicative of a limited negative binding cooperativity. Analysis of the data according to an allosteric ternary complex model revealed that the estimated affinity of each Org compound was not significantly different

when the radioligand was [³H]CP 55,940 or [³H]SR 141716A. However, the estimated cooperativity factor for the interaction between modulator and radioligand was greater than 1 when determined against [³H]CP 55,940 and less than 1 when determined against [³H]SR 141716A. [³H]CP 55,940 dissociation kinetic studies also validated the allosteric nature of the Org compounds, because they all significantly decreased radioligand dissociation. These data suggest that the Org compounds bind allosterically to the CB₁ receptor and elicit a conformational change that increases agonist affinity for the orthosteric binding site. In contrast to the binding assays, however, the Org compounds behaved as insurmountable antagonists of receptor function; in the reporter gene assay, the guanosine 5'-O-(3-[³⁵S]thio)triphosphate binding assay and the mouse vas deferens assay they elicited a significant reduction in the E_{max} value for CB₁ receptor agonists. The data presented clearly demonstrate, for the first time, that the cannabinoid CB₁ receptor contains an allosteric binding site that can be recognized by synthetic small molecule ligands.

Mammalian tissues express at least two types of cannabinoid receptor, CB₁ and CB₂, both G protein-coupled (for re-

view, see Howlett et al., 2002). CB₁ receptors are found predominantly at central and peripheral nerve terminals where they mediate inhibition of transmitter release. Endogenous ligands for these receptors also exist. These "endocannabinoids" are all eicosanoids, prominent examples including arachidonylethanolamide (anandamide) and 2-arachidonoyl glycerol, both of which are synthesized on demand, removed from their sites of action by tissue uptake processes and metabolized by intracellular enzymes (Pertwee and Ross,

ABBREVIATIONS: CB, cannabinoid; GPCR, G protein-coupled receptor; TCM, ternary complex model; CNS, central nervous system; WIN 55,212, (+)-WIN 55,212-2 [(*R*)-(+)-[2,3-dihydro-5-methyl-3-(4-morpholinylmethyl)pyrrolo[1,2,3-*de*]-1,4-benzoxazin-6-yl]-1-naphthalenylmethanone]; CP 55,940, (1*R*,3*R*,4*R*)-3-[2-hydroxy-4-(1,1-dimethylheptyl)phenyl]-4-(3-hydroxypropyl)cyclohexan-1-ol; SR 141716A, *N*-(piperidin-1-yl)-5-(4-chlorophenyl)-1-(2,4-dichlorophenyl)-4-methyl-1*H*-pyrazole-3-carboximide hydrochloride; BSA, bovine serum albumin; DTT, dithiothreitol; Gpp(NH)p, guanosine 5'-(β,γ-imido)triphosphate; GTPγS, guanosine 5'-O-(3-thio)triphosphate; Org 27569-0, 5-chloro-3-ethyl-1*H*-indole-2-carboxylic acid [2-(4-piperidin-1-yl-phenyl)-ethyl]-amide; Org 27759-0, 3-ethyl-5-fluoro-1*H*-indole-2-carboxylic acid [2-(94-dimethylamino-phenyl)-ethyl]-amide; Org 29647-1, 5-chloro-3-ethyl-1*H*-indole-2-carboxylic acid (1-benzyl-pyrrolidin-3-yl)-amide, 2-enedioic acid salt; DMSO, dimethyl sulfoxide.

2002). There is ample evidence for a role of the endocannabinoid system in a number of physiological processes, including cardiovascular regulation, appetite control, learning, and memory and pain processing (for review, see Ross, 2003; Di Marzo et al., 2004). Within the brain, the distribution of CB₁ receptors is heterogeneous, accounting for several well documented pharmacological properties of CB₁ receptor agonists. For example, the cerebral cortex, hippocampus, lateral caudate-putamen, substantia nigra, pars reticulata, globus pallidus, entopeduncular nucleus, and the molecular layer of the cerebellum are all populated with particularly high concentrations of CB₁ receptors. CB₁ receptor ligands have therapeutic potential in a range of disorders, including obesity, nicotine addiction, pain, inflammation, gastrointestinal disorders, multiple sclerosis, psychosis, schizophrenia, and osteoporosis.

The traditional view of G protein-coupled receptor (GPCR) signaling posits that agonists initiate signaling by binding to a site on the GPCR that has specifically evolved to recognize the endogenous agonist for that receptor; this site has been defined as the *orthosteric* binding site (Neubig et al., 2003). It is now recognized, however, that GPCRs may also contain *allosteric* binding sites for endogenous and/or synthetic ligands (Christopoulos and Kenakin, 2002). Allosteric sites are topographically distinct from the orthosteric site; hence, the structural features that determine ligand binding to allosteric sites are different from those of orthosteric ligands. In contrast to the direct effects on receptor function that are mediated by orthosteric ligands, allosteric drugs act by modulating receptor activity through conformational changes in the receptor that are transmitted from the allosteric to the orthosteric site and/or to effector coupling sites (Christopoulos, 2002).

The simplest allosteric interaction can be described by the allosteric ternary complex model (TCM; Fig. 1), where the effect of an allosteric ligand is to change the affinity of an orthosteric ligand for the receptor, and vice versa (Ehlert, 1988; Lazareno and Birdsall, 1995). From a mechanistic standpoint, allosteric modulation of affinity reflects a conformational change in the receptor that may lead to an alteration in the dissociation kinetics of a preformed orthosteric ligand-receptor complex; this effect on dissociation kinetics cannot occur if interacting ligands recognize the same binding site and is thus diagnostic of an allosteric effect (Kostenis and Mohr, 1996; Christopoulos, 2000). More recently, data

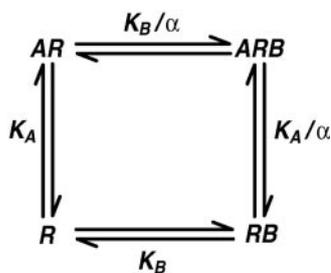

Fig. 1. The allosteric TCM, where R denotes the receptor; A and B denote the orthosteric and allosteric ligands, respectively; K_A and K_B denote their respective equilibrium dissociation constants; and α denotes a cooperativity factor that governs the magnitude and direction of the allosteric interaction between the two ligands when they both occupy the receptor. Values of α greater than 1 denote positive binding cooperativity (enhanced affinity), values less than 1 denote negative binding cooperativity, and values equal to 1 denote neutral binding cooperativity.

have been presented to suggest that allosteric modulators may affect the *efficacy* of orthosteric ligands in addition to, or independently of, effects on orthosteric ligand binding, necessitating the development of more complex models of allosteric modulation (Christopoulos and Kenakin, 2002, and references therein).

To date, the main principle underlying GPCR-based drug discovery has invariably been the optimization of lead molecules toward the orthosteric site on the GPCR to obtain selectivity of action. However, allosteric modulators offer advantages not readily available with orthosteric ligands. For example, allosteric drugs that affect affinity (but not efficacy) would be advantageous in that they would boost or dampen the effect of the endogenous ligand without disrupting the inherent spatial and temporal patterns of physiological signaling (May and Christopoulos, 2003). CB₁ receptor pharmacology is the subject of intense academic and commercial research effort directed at the treatment of obesity (Horvath, 2003), pain (Pertwee, 2001; Iversen and Chapman, 2002), inflammation (Rice et al., 2002), osteoporosis (Idris et al., 2005), cancer (Bifulco and Di Marzo, 2002), multiple sclerosis (Pertwee, 2002), and cardiovascular disorders (Randall et al., 2002). There is ample evidence that the levels of endocannabinoids are altered in these pathophysiological situations. Allosteric enhancers of the cannabinoid CB₁ receptor would thus offer the prospect of producing clinically useful compounds that do not display the CNS side effects that are characteristic of direct receptor agonism. In this investigation, we provide the first evidence for an allosteric binding site on the cannabinoid CB₁ receptor, as revealed by the pharmacology and mode of action of a novel class of synthetic small molecules (Fig. 2).

Materials and Methods

Materials

(+)-WIN 55,212-2 (WIN 55,212) and CP 55,940 were obtained from Tocris Cookson, Inc. (Bristol, UK), and SR 141716A was from the National Institute on Drug Abuse (Bethesda, MD). Bovine serum albumin (BSA), cell culture media, dithiothreitol, nonenzymatic cell dissociation solution, GDP, Gpp(NH)p, GTP γ S, G418 (Geneticin), L-glutamine, Krebs' salts, penicillin/streptomycin, Tris buffer, and Triton X-100 were all obtained from Sigma-Aldrich. [³H]CP 55,940 (128 Ci/mmol) and [³⁵S]GTP γ S (1250 Ci/mmol) were obtained from GE Healthcare (Little Chalfont, Buckinghamshire, UK). [³H]SR 141716A (44 Ci/mmol) was obtained from the National Institute on Drug Abuse. Three novel compounds were from Organon Research (Newhouse, Lanarkshire, Scotland): Org 27569-0, Org 27759-0, and Org 29647-1.

Radioligand Binding Assays

Mouse Brain Membrane Preparation. Whole brains from adult male MF1 mice were suspended in centrifugation buffer (320 mM sucrose, 2 mM EDTA, and 5 mM MgCl₂), and the tissues were homogenized with an Ultra-Turrex homogenizer. Tissue homogenates were centrifuged at 1600g for 10 min, and the resulting supernatant was collected. This pellet was resuspended in centrifugation buffer centrifuged as described above, and the supernatant was collected. Supernatants were combined before undergoing further centrifugation at 28,000g for 20 min. The supernatant was discarded, and the pellet was resuspended in buffer A (50 mM Tris, 2 mM EDTA, 5 mM MgCl₂ at pH 7.0) and incubated at 37°C for 10 min. After the incubation, the suspension was centrifuged for 20 min at 23,000g. After resuspending the pellet in buffer A, the suspension

was incubated for 40 min at room temperature before a final centrifugation for 15 min at 11,000g. The final pellet was resuspended in buffer B (50 mM Tris, 1 mM EDTA, and 3 mM MgCl₂), and the final protein concentration, determined by Bio-Rad DC kit, was 1 mg/ml. All centrifugation procedures were carried out at 4°C. Prepared brain membranes were stored at -80°C and defrosted on the day of the experiment.

Equilibrium Binding Assays. Binding assays were performed with the CB₁ receptor agonist [³H]CP 55,940 (0.7 nM) and the CB₁ receptor antagonist [³H]SR 141716A (1.2 nM), 1 mg/ml BSA and 50 mM Tris buffer containing 0.1 mM EDTA and 0.5 mM MgCl₂, pH 7.4, in a total assay volume of 500 μl. Binding was initiated by the addition of mouse brain membranes (30 μg). Assays were carried out at 37°C for 60 min before termination by addition of ice-cold wash buffer (50 mM Tris buffer and 1 mg/ml BSA) and vacuum filtration using a 24-well sampling manifold (Brandel cell harvester) and Whatman GF/B glass-fiber filters (Whatman, Maidstone, UK) that had been soaked in wash buffer at 4°C for 24 h. Each reaction tube was washed five times with a 4-ml aliquot of buffer. The filters were oven-dried for 60 min and then placed in 5 ml of scintillation fluid (Ultima Gold XR; PerkinElmer Life and Analytical Sciences, Boston, MA), and radioactivity was quantitated by liquid scintillation spectrometry. Specific binding was defined as the difference between the binding that occurred in the presence and absence of 1 μM concentrations of the corresponding unlabeled ligand and was 70 to 80% of the total binding.

Dissociation Kinetics. Dissociation kinetic assays were performed with the CB₁ receptor agonist [³H]CP 55,940 (0.7 nM), 1 mg/ml BSA, and 50 mM Tris buffer containing 0.1 mM EDTA and 0.5 mM MgCl₂, pH 7.4, total assay volume 500 μl. We used the "isotopic dilution" method to measure the dissociation rate constant for [³H]CP 55,940 from brain membranes (Christopoulos, 2000). [³H]CP 55,940 (0.7 nM) was incubated with mouse brain membranes (30 μg) for 60 min at 25°C. Dissociation was initiated by the addition of 1 μM unlabeled ligand in the presence and absence of test compounds. Dissociation times of 0.5 to 120 min at 25°C were used. To determine the nonspecific binding, experiments were also performed in the presence of a 1 μM concentration of the unlabeled ligand. Binding was terminated by addition of ice-cold wash buffer (50 mM Tris buffer and 1 mg/ml BSA) and vacuum filtration using a 24-well sampling manifold (Brandel cell harvester) and Whatman GF/B glass-fiber filters that had been soaked in wash buffer at 4°C for 24 h. Each reaction tube was washed five times with a 4-ml aliquot of buffer. The filters were oven-dried for 60 min and then placed in 5 ml

of scintillation fluid (Ultima Gold XR), and radioactivity was quantitated by liquid scintillation spectrometry. Specific binding was defined as the difference between the binding that occurred in the presence and absence of 1 μM unlabeled ligand and was 70 to 85% of the total binding.

Mouse Isolated Vas Deferens Assay. Vasa deferentia were obtained from albino MF1 mice weighing 26 to 40 g. Each tissue was mounted in a 4-ml organ bath at an initial tension of 0.5g. The baths contained Mg²⁺-free Krebs' solution that was kept at 35°C and bubbled with 95% O₂ and 5% CO₂. The composition of the Krebs' solution was 118.2 mM NaCl, 4.75 mM KCl, 1.19 mM KH₂PO₄, 25.0 mM NaHCO₃, 11.0 mM glucose, and 2.54 mM CaCl₂·6H₂O. Isometric contractions were evoked by stimulation with 0.5-s trains of three pulses of 110% maximal voltage (train frequency, 0.1 Hz; pulse duration, 0.5 ms) through a platinum electrode attached to the upper end and a stainless steel electrode attached to the lower end of each bath. Stimuli were generated by a Grass S48 stimulator and then amplified (Med-Lab channel attenuator) and divided to yield separate outputs to eight organ baths (Med-Lab StimuSplitter). Contractions were monitored by computer using a data recording and analysis system (MacLab) that was linked via preamplifiers (Macbridge) to UF1 transducers. After placement in an organ bath, each tissue was subjected to a stimulation-free period of 15 min and then stimulated for 10 min. Tissues were then subjected to alternate periods of stimulation (5 min) and rest (10 min) until consistent twitch amplitudes were obtained. This equilibration procedure was followed by a stimulation-free period of 10 min. Tissues were then stimulated for 10 min after which the stimulator was switched off, and the Org compound or its vehicle was added. Thirty minutes later, the first addition of the nonselective CB₁/CB₂ receptor agonist WIN 55,212 was made. Additions of WIN 55,212 were made cumulatively at 5-min intervals without washout, the tissues being stimulated for the final 2 min of exposure to each concentration of this agonist. Org compounds were dissolved in DMSO, and WIN 55,212 was dissolved in a solution consisting of 50% DMSO and 50% saline. By themselves, these vehicles did not inhibit the twitch response. Drug additions were made in a volume of 10 μl.

The measured response was WIN 55,212-induced inhibition of electrically-evoked contractions of the mouse isolated vas deferens. The Org compounds (or their vehicle, DMSO) were added 30 min before WIN 55,212 that was then added cumulatively using a 15-min dose cycle. Thus, we constructed WIN 55,212 concentration-response curves in the presence of DMSO or the Org compounds.

The degree of inhibition of evoked contractions induced by WIN

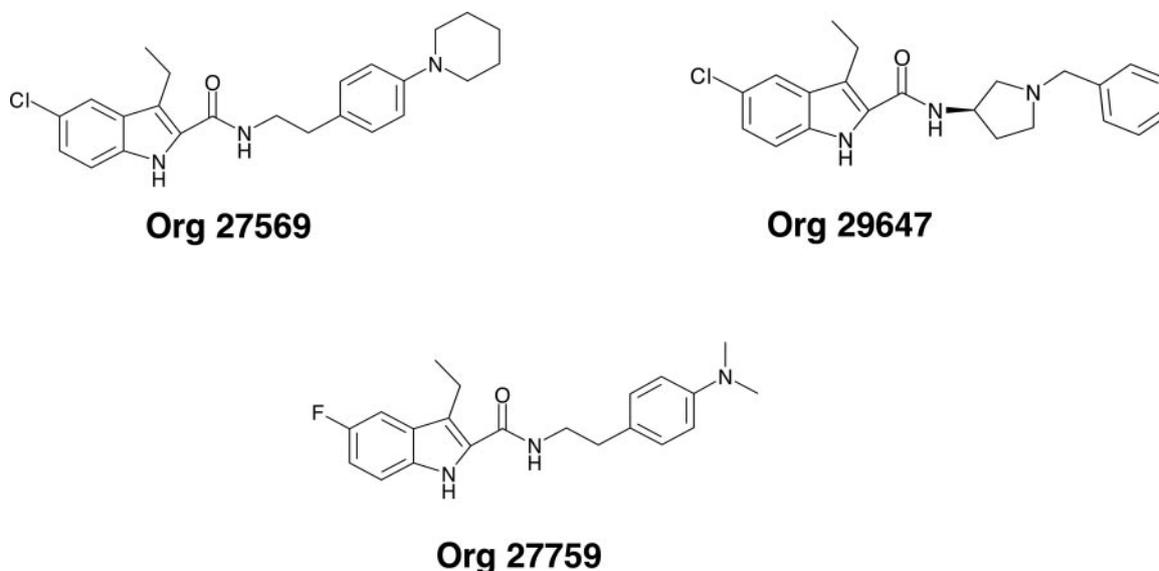

Fig. 2. Structure of Organon compounds Org 27569-0, 5 Org 27759-0, and Org 29647-1.

55,212 was calculated in percentage terms by comparing the amplitude of the twitch response after each addition of WIN 55,212 with its amplitude immediately before the first addition of this agonist.

[³⁵S]GTPγS Binding Assay. Mouse brain membranes (5 μg of protein) were preincubated for 30 min at 30°C with adenosine deaminase (0.5 U/ml). The membranes were then incubated with the agonist with vehicle or modulator for 60 min at 30°C in assay buffer (50 mM Tris-HCl, 50 mM Tris-base, 5 mM MgCl₂, 1 mM EDTA, 100 mM NaCl, 1 mM dithiothreitol, and 0.1% BSA) in the presence of 0.1 nM [³⁵S]GTPγS and 30 μM GDP, in a final volume of 500 μl. Binding was initiated by the addition of [³⁵S]GTPγS. Nonspecific binding was measured in the presence of 30 μM GTPγS. The reaction was terminated by rapid vacuum filtration (50 mM Tris-HCl, 50 mM Tris-base, and 0.1% BSA) using a 24-well sampling manifold (Brandel cell harvester) and GF/B filters that had been soaked in buffer (50 mM Tris-HCl, 50 mM Tris-base, and 0.1% BSA) for at least 24 h. Each reaction tube was washed six times with a 1.2-ml aliquot of ice-cold wash buffer. The filters were oven-dried for at least 60 min and then placed in 5 ml of scintillation fluid (Ultima Gold XR). Radioactivity was quantified by liquid scintillation spectrometry.

CB₁ Reporter Gene Assay

Test compounds were all prepared in glass vials and were dissolved in DMSO to give a concentration of 10 mM. The solutions were then diluted in nutrient mix F-12 media with 3% BSA to give a range of concentrations from 0.1 mM to 0.1 nM (10× stocks) for addition to the assay (BSA final concentration, 0.3%). The DMSO concentration did not exceed 0.1% by volume. For all aqueous solutions, ultrapure water (Milli-Q quality) was used.

Chinese hamster ovary cells, expressing the human CB₁ receptor were transfected with a luciferase reporter gene under the control of seven AP1 repeats (Stratagene, La Jolla, CA). Single cell-derived clones were maintained in Ham's F-12 nutrient mix (1:1) with 10% FetaClone II, 50 U/50 μg/ml penicillin/streptomycin, 1 μg/ml fungizone, 0.2 μg/ml geneticin (disulfate salt), and 0.5 μg/ml hygromycin at 37°C/5% CO₂. The day before the assay, the cells were harvested using trypsin-EDTA and then pelleted by centrifugation (5 min, 20°C spin at 600g). The pellet was resuspended in phenol red/serum-free Dulbecco's modified Eagle's medium/Ham's F-12 nutrient mix containing 50 units of penicillin, 50 μg/ml streptomycin, and 1 μg/ml Fungizone. The cells were then seeded into white 96-well plates (CulturPlates; PerkinElmer Life and Analytical Sciences) at a density of 3 × 10⁴ cells per well (100-μl final volume). Cells were incubated overnight (approximately 18 h at 37°C, 5% CO₂, 95% air) before assay.

Ten microliters of a 10× stock of test compound was added directly to the relevant wells, and the plates were incubated at 37°C for 5 h. Then, under subdued light, 100 μl of LucLite reagent (reconstituted per instructions from PerkinElmer Life and Analytical Sciences) was added to each well. The plates were covered with Top Seal and then incubated at room temperature for 5 min before counting on the PerkinElmer Life and Analytical Sciences TopCount (single photon counting, 0.01-min count time, no count delay). For modulator studies, the cells were preincubated for 5 min with the test compound and then agonist. Incubations and luciferase assays were then performed as detailed above.

Data Analysis

Radioligand competition binding isotherms for the interaction between orthosteric ligands were analyzed using Prism 4.01 (Graph-Pad Software Inc., San Diego, CA) according to the following logistic function:

$$Y = \frac{(\text{top} - \text{bottom})[I]}{[I] + \text{IC}_{50}} \quad (1)$$

where Y denotes the percentage of specific binding; top and bottom denote the maximal and minimal asymptotes, respectively; $[I]$ de-

notes the inhibitor concentration; and IC_{50} denotes the inhibitor potency (midpoint location) parameter.

The interaction between each radioligand and the test modulators was analyzed according to the following allosteric ternary complex model of interaction:

$$Y = \frac{[A]}{[A] + \frac{K_A(1 + [B]/K_B)}{(1 + \alpha[B]/K_B)}} \quad (2)$$

where Y denotes the fractional specific binding, $[A]$ and $[B]$ denote the concentration of orthosteric and allosteric ligands, respectively, K_A and K_B denote their respective equilibrium dissociation constants, and α denotes a cooperativity factor that governs the magnitude and direction of the allosteric interaction between the two ligands when they both occupy the receptor. For this analysis, values of $[A]$ and K_A were fixed as constants (the latter determined from previous saturation binding assays), whereas values of α and K_B were determined by nonlinear regression.

For the dissociation kinetic experiments, the decay in radioligand binding over time was analyzed according to the following two-phase exponential decay model:

$$Y = \text{Span1} \times e^{-k_1 \times t} + \text{Span2} \times e^{-k_2 \times t} + \text{Plateau} \quad (3)$$

where Span1 and Span2 denote the percentage of each phase; plateau denotes the minimal asymptotic value; and k_1 and k_2 denote the rate constants for the components defined by Span1 and Span2 , respectively. An extra-sum-of-squares (F test) was used to determine whether the data were significantly better fitted to this model compared with a simpler model characterized by a single Span and k value.

Concentration-response data were fitted empirically to the following four-parameter logistic equation:

$$Y = \text{basal} + \frac{(E_{\text{max}} - \text{basal})[A]^{n_H}}{[A]^{n_H} + [10^{-\text{pEC}_{50}}]^{n_H}} \quad (4)$$

where Y denotes effect; $[A]$ the concentration of agonist; n_H the Hill slope, pEC_{50} the negative logarithm of the midpoint location parameter; and E_{max} and basal the upper and lower asymptotes, respectively. An extra-sum-of-squares (F test) was used to determine whether the data were significantly better fitted assuming separate values for the basal and n_H parameters across each data set in the absence relative to presence of test compound, compared with common values for each parameter. In practice, all affinity (K_B), potency (EC_{50}), and cooperativity (α) parameters were estimated as logarithms (Christopoulos, 1998).

Operational Model-Fitting. The functional interaction between test compounds and the orthosteric agonist WIN 55,212 in the mouse isolated vas deferens was fitted to the following operational model of allosterism (see *Appendix* for derivation):

$$E = \frac{E_m \tau^n [A]^n \left(1 + \frac{\alpha \beta [B]}{K_B}\right)^n}{\left[[A] \left(1 + \frac{\alpha [B]}{K_B}\right) + K_A \left(1 + \frac{[B]}{K_B}\right) \right]^n + \tau^n [A]^n \left(1 + \frac{\alpha \beta [B]}{K_B}\right)^n} \quad (5)$$

where E denotes the effect, β denotes an empirical proportionality constant that quantifies the change in stimulus imparted to the receptor by the agonist in the presence of modulator, E_m denotes the maximum possible effect, τ is an operational measure of orthosteric ligand efficacy, and n is a logistic slope factor that governs the shape of the stimulus-response function. $[A]$, K_A , and α are as defined above.

Statistics

Values have been expressed as means and variability as S.E.M. or as 95% confidence limits. Mean values have been compared using

Student's unpaired *t* test or analysis of variance followed by Dunnett's test or the Newman-Keuls test. A *P* value <0.05 was considered significant.

Results

Equilibrium Binding Assays. In equilibrium binding experiments with the orthosteric agonist probe [³H]CP 55,940, unlabeled CP 55,940 competed with the radioligand according to a simple one-site competition model, characterized by a pIC₅₀ value of 9.54 ± 0.09 (*n* = 5). In contrast, the test compounds all produced a significant, but saturable, increase in the level of specific [³H]CP 55,940 binding (Fig. 3A), the most marked effect being observed with Org 27569.

When the inverse agonist [³H]SR 141716A was used as the orthosteric probe, a different profile of activity was observed. As expected, unlabeled SR 141716A displayed simple mass-action behavior, competing with the radioligand and yielding a pIC₅₀ value of 9.22 ± 0.02 (*n* = 4). Unlike their effects on agonist binding, the test compounds (at concentrations up to their solubility limit) also produced a significant decrease in the equilibrium binding of [³H]SR 141716A (Fig. 3B). However, the reduction in specific radioligand binding mediated by the test compounds seemed saturable and incomplete, which is at odds with the expectations of simple competitive behavior.

Both agonist and antagonist radiolabel binding data were fitted to the allosteric TCM (Fig. 1; eq. 2, and the resulting parameters are shown in Table 1 where it can be seen that there is no significant difference in the estimated pK_B value for each compound at the putative allosteric site on the CB₁ receptor when tested against [³H]CP 55,940 compared with when [³H]SR 141716A was used as the orthosteric probe. In contrast, the [³H]CP 55,940 data were characterized by α values greater than 1, indicative of a positive allosteric modulation of the binding of radiolabeled agonist, whereas those of the [³H]SR 141716A data set were less than 1, indicating a negative allosteric modulation of the binding of the inverse agonist.

Dissociation Kinetic Assays. To validate that the test compounds were indeed allosteric modulators of the CB₁ receptor, [³H]CP 55,940 dissociation kinetic experiments were performed. In the absence of test compound, the dissociation of [³H]CP 55,940 was significantly (*P* < 0.0001; *F* test) biphasic (Fig. 4). The dissociation rate constants and the percentages for the two phases are listed in Table 2. When this experiment was performed in the presence of each of the test compounds, a concentration-dependent reduction was observed in each of the slow and fast radioligand dissociation rate constants (Fig. 4, A–C; Table 2), with no significant effect on the percentage of either phase. This finding is consistent with an alteration of receptor conformation that reduces orthosteric ligand dissociation without affecting G protein coupling status. In contrast, the addition of the nonhydrolysable GTP analog Gpp(NH)p (40 μM), which is known to uncouple complexes between receptors and G-protein, did not have a significant effect on [³H]CP 55,940 dissociation rates, but it did significantly reduce the percentage of the slowly dissociating component of binding, from 59.03 ± 3.03 to 16.10 ± 2.93%

Mouse Vas Deferens. The effects of the modulators on CB₁ receptor function were initially investigated using the mouse vas deferens as an *in vitro* model of CB₁ receptor activity. As shown in Fig. 5, A to C, the compounds by themselves neither inhibited nor enhanced electrically evoked contractions at the concentrations that were used (up to 1 μM), suggesting that they are neither allosteric agonists nor inverse agonists. This is in contrast to the effect of the established CB₁ receptor inverse agonist SR 141716A, which significantly increases electrically evoked contractions under the same assay conditions (Fig. 5D). The functional effects of the compounds on the inverse agonism displayed by SR 141716A in the mouse vas deferens are the subject of ongoing investigation.

When tested against the CB₁ agonist WIN 55,212, an interesting effect was observed in the presence of modulator. In particular, the maximal agonist effect (*E*_{max}) of WIN 55,212 to inhibit the electrically evoked contractions of the mouse

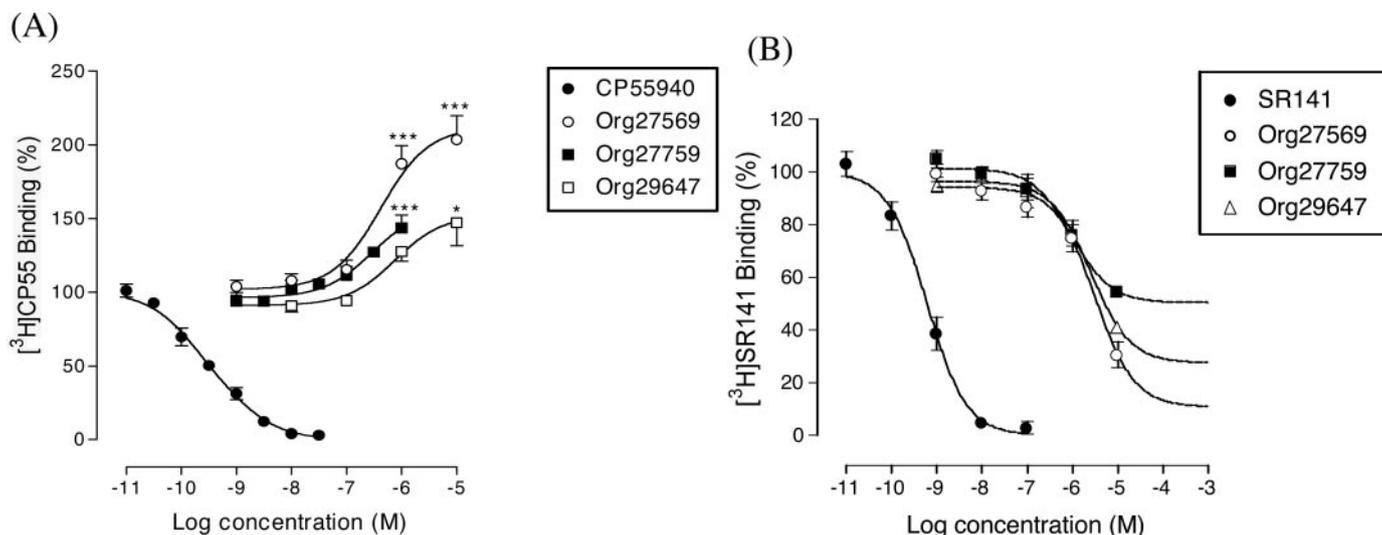

Fig. 3. Equilibrium binding of [³H]CP 55,940 (0.7 nM) (A) and [³H]SR 141716A (1.2 nM) (B) in mouse brain membranes in the presence of unlabeled ligand or the Org 27569, Org 29647, and Org 27759. Each symbol represents the mean percentage of specific binding ± S.E.M. (*n* = 4–6). *, *P* < 0.05 and ***, *P* < 0.001, one-sample *t* test. Curves superimposed on the data represent the best fits of eq. 1 (orthosteric ligands) or eq. 2 (allosteric modulators).

vas deferens was significantly reduced by each of Org 27569, Org 27759, and Org 29647, indicative of an insurmountable mode of antagonism (Table 3); with the exception of 1 μ M Org 27569 and Org 27759, the compounds did not significantly alter the pEC₅₀ values for WIN 55,212 (Table 3).

To investigate whether the effects of the compounds were unique to cannabinoid receptors, we conducted experiments with the α_2 adrenoceptor agonist clonidine. In the presence of DMSO, clonidine inhibited electrically evoked contractions of the mouse vas deferens with a pEC₅₀ of 9.00 ± 0.14 and E_{\max}

of 83% (95% confidence limits, 77.9–88.1). These values were not significantly different in the presence of 1 μ M Org 27569, with the pEC₅₀ and E_{\max} being 8.66 ± 0.11 and 77% (95% confidence limits, 70.6–82.7), respectively.

To gain further insight into the apparent dichotomy between modulators' effects on agonist affinity, on the one hand, and efficacy, on the other, the data were globally fitted to an operational model of allosterism (see *Appendix*). This analysis was based on the following assumptions. First, WIN 55,212 was assumed to be a full agonist at the CB₁ receptor

TABLE 1

Allosteric TCM binding parameters for various modulators at mouse brain CB₁ receptors

pK_B is the negative logarithm of the equilibrium dissociation constant for the allosteric modulator at the free receptor, determined using nonlinear regression according to eq. 2 under *Materials and Methods*. Values represent the mean \pm S.E.M. of four to eight experiments. For these analyses, the negative logarithm of the K_A value (eq. 2) was fixed to nine for each radioligand, based on previous saturation binding assays. Log α is the logarithm of the cooperativity factor. α is the antilogarithm (geometric mean) of the cooperativity factor with range in parentheses, based on the estimated log α values.

Radioligand & Parameter	Allosteric Modulator		
	Org 27569	Org 27759	Org 29647
³ H]CP 55,940			
pK _B	5.67 \pm 0.23	6.31 \pm 0.32	5.78 \pm 0.26
Log α	1.14 \pm 0.17	0.47 \pm 0.10	0.44 \pm 0.07
α	14 (9.3–20.4)	3 (2.3–3.7)	2.8 (2.3–3.2)
³ H]SR 141617A

Log α	-1.04 \pm 0.25	-0.48 \pm 0.10	-0.44 \pm 0.16
α	0.09 (0.05–0.16)	0.33 (0.26–0.42)	0.36 (0.25–0.52)

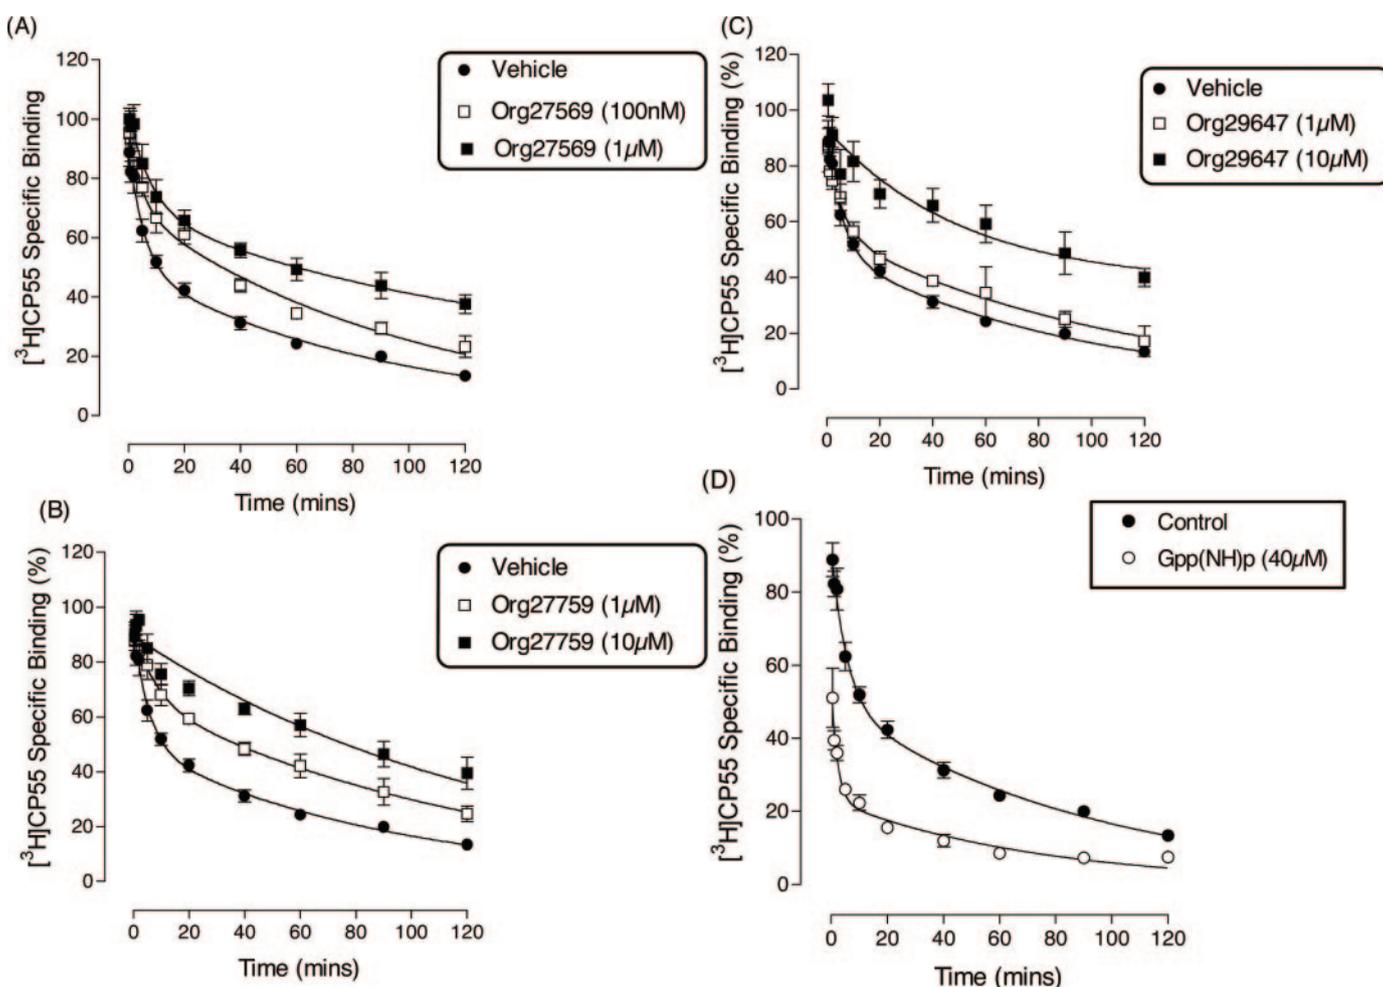

Fig. 4. Dissociation of ³H]CP 55,940 (0.7 nM) in mouse brain membranes in the presence of vehicle or Org 27569 (A), Org 27759 (B), Org 29647 (C), or Gpp(NH)p (D). Each symbol represents the mean percentage of specific binding \pm S.E.M. ($n = 4-8$).

(Pertwee, 1997): the E_{\max} value of approximately 80% of the maximal tissue inhibition presumably represents the maximal inhibition that can be mediated by CB₁ receptor activation. Second, the G protein-coupled receptor active state, which is promoted by agonist binding, was assumed to be extremely transient, as expected for intact cells (Ehlert and Rathbun, 1990), such that the affinity estimate for WIN 55,212 reflected its K_A value for the uncoupled form of the receptor.

The results of this analysis are shown in Fig. 6 and Table 4 and allow us to reconcile our observations with a mechanism whereby the binding cooperativity (α value) between each modulator and WIN 55,212 is positive, consistent with the enhancement of agonist binding observed in the [³H]CP 55,940 binding experiments, but the signaling efficiency of the ARB ternary complex (Fig. 1) is significantly impaired (β

values tend toward or equal 0). Together, these two mechanisms can account for an insurmountable antagonism of receptor function with minimal effect on full agonist potency.

[³⁵S]GTP γ S Binding Assay. The insurmountable antagonism mediated by the modulators in the intact mouse vas deferens functional assay is also evident when receptor activity is monitored using a more proximal measure of receptor-effector coupling. In the presence of vehicle, CP 55,940 produced a stimulation of [³⁵S]GTP γ S binding that was 78.65% (95% confidence limits, 66.7–90.6) above basal binding with a pEC₅₀ value of 7.93 ± 0.14 (Fig. 7A). In the presence of 100 nM Org 29647, the curve was shifted to the right, although there was no statistically significant effect on E_{\max} or pEC₅₀, with these values being 73.70% (95% confidence limits, 36.8–110) and 7.54 ± 0.48 , respectively. However, when the concentration of Org 29647 was increased to

TABLE 2

Dissociation rate constants for [³H]CP 55,940 at mouse brain CB₁ receptors in the absence or presence of allosteric modulators

Parameter values were estimated using global nonlinear regression analysis, with the minimal plateau value constrained to 0. An extra-sum-of-squares (F test) revealed that all data sets were adequately fitted assuming common values for the percentage of the slowly dissociating state (Span1, 59.03 \pm 3.03%) and the fast dissociating state (Span2, 35.75 \pm 2.97%). k_1 (slow) and k_2 (fast) are the dissociation rate constants for the slow and fast dissociating states, respectively.

	k_1 (slow)	Half-Life Slow	k_2 (fast)	Half-Life Fast
	$\times 10^{-2} \text{ min}^{-1}$	min	min^{-1}	min
Vehicle	1.40 \pm 0.08	49.4 (55.6–44.5)	0.294 \pm 0.037	2.35 (3.14–1.88)
Org 27569 (100 nM)	0.79 \pm 0.03**	87.8 (94.2–82.2)	0.091 \pm 0.006**	7.59 (8.69–6.74)
Org 27569 (1 μ M)	0.36 \pm 0.03**	194 (235–165)	0.056 \pm 0.005**	12.43 (15.31–10.44)
Org 27759 (1 μ M)	0.64 \pm 0.03**	108 (119–99)	0.099 \pm 0.008**	7.03 (8.29–6.11)
Org 27759 (10 μ M)	0.28 \pm 0.03**	249 (304–210)	0.042 \pm 0.004**	16.36 (19.6–14.03)
Org 29647 (1 μ M)	0.98 \pm 0.04**	71.0 (76.5–66.2)	0.344 \pm 0.026	2.01 (2.36–1.75)
Org 29647 (10 μ M)	0.26 \pm 0.004**	264 (369–205)	0.036 \pm 0.005**	19.53 (26.01–15.64)

** $P < 0.01$, one-way analysis of variance followed by Dunnett's post test.

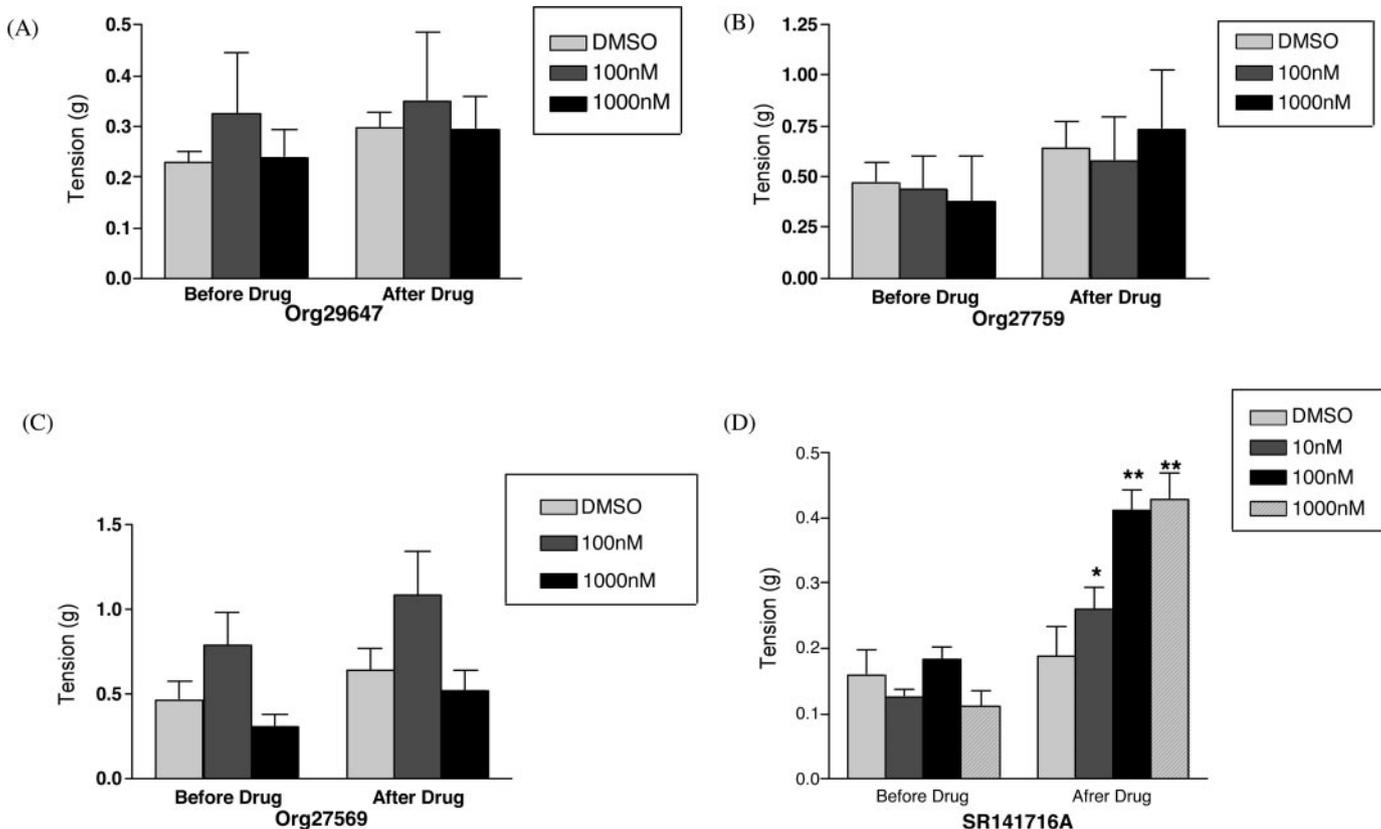

Fig. 5. Effect of the Org compounds (A–C) and SR141716A (D) on the height of electrically evoked contractions of the mouse isolated vas deferens. The figures show the g tension before adding either vehicle (DMSO) or drug \pm S.E.M. *, $P < 0.05$; **, $P < 0.01$, Student's unpaired t test.

1 μ M, the ability of CP 55,950 to stimulate [³⁵S]GTP γ S turnover was completely abrogated.

In the presence of vehicle the endogenous cannabinoid anandamide produced a stimulation of [³⁵S]GTP γ S binding that was 61.1% (95% confidence limits, 53.8–68.3) above basal binding with a pEC₅₀ value of 6.62 \pm 0.15 (Fig. 7B). In the presence of 100 nM Org 27569, the curve was shifted to the right, although there was no statistically significant effect on E_{\max} of 59.8% (95% confidence limits, 49.9–69.6). However, when the concentration of Org 27569 was increased to 1 μ M, the ability of anandamide to stimulate [³⁵S]GTP γ S turnover was significantly attenuated, the E_{\max} being 17.0% (95% confidence limits, 10.2–23.7).

Human CB₁ Receptor Reporter Gene Assay. To confirm that the effect of the modulators was not species-specific, additional functional assays were performed using cloned human CB₁ receptors. In the luciferase reporter assay, the Org compounds all behaved as insurmountable antagonists of CP 55,940 (Fig. 8), causing a concentration-dependent reduction in the agonist E_{\max} value (Table 5).

Discussion

The Org compounds that we have identified display a number of characteristics commonly associated with allosteric modulators, including 1) either enhancement or inhibition of orthosteric CB₁ ligand binding depending on the nature of the orthosteric probe, 2) a slowing of the dissociation rate constant(s) for [³H]CP 55,940 from the occupied CB₁ receptor, and 3) a noncompetitive inhibition of CB₁ receptor orthosteric agonist efficacy.

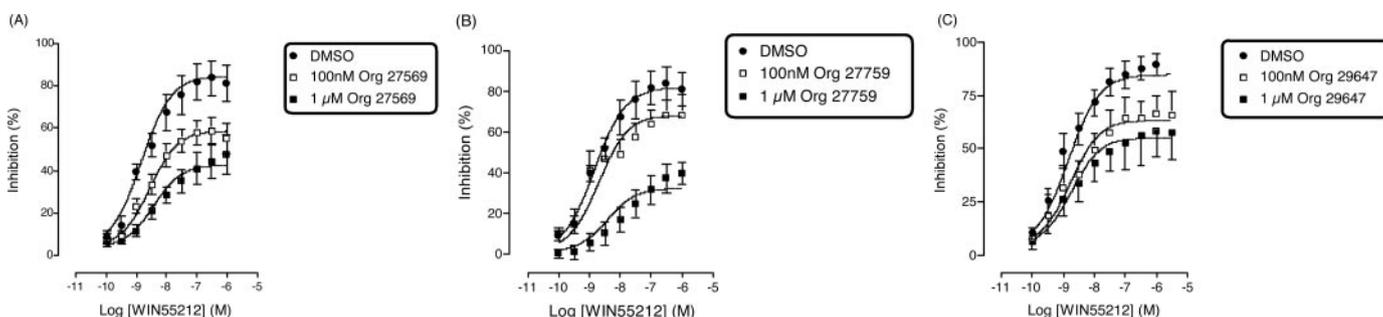

Fig. 6. Inhibition of electrically evoked contractions of the mouse isolated vas deferens by WIN 55,212 in the presence of the indicated Org compounds. Each symbol represents the mean percent inhibition \pm the S.E.M. ($n = 6-8$). Curves superimposed on the data represent the best global fit of the operational model of allosterism (eq. 5).

In equilibrium binding assays, the Org compounds significantly increased the binding of the CB₁ receptor agonist [³H]CP 55,940, indicative of a positively cooperative allosteric effect. In contrast, the same compounds caused a significant, but incomplete, decrease in the specific binding of the CB₁ receptor inverse agonist [³H]SR 141716A, indicative of a limited negative binding cooperativity (Christopoulos and Kenakin, 2002). The most common mechanistic description of inverse agonism is based on the premise that GPCRs exist in at least two conformational states, an inactive R and an active R* state (Pertwee 2005). In this model, agonists have higher affinity for the R* state and shift the equilibrium toward R* resulting in G protein activation and an increase in GDP/GTP exchange. In contrast, inverse agonists bind preferentially to the R state, resulting in a decrease in constitutive activity. We used [³H]CP 55,940 to selectively label the R* state, most likely present as the complexed R*G state in our membrane-based assays, and [³H]SR 141716A to label the R state of the receptor. Analysis of the data according to the allosteric TCM revealed that the estimated pK_B values for the Org compounds were not significantly different when the radioligand was [³H]CP 55,940, or [³H]SR 141716A (Table 1). Because these affinity values represent the dissociation constant for the modulator binding to the allosteric site on the free (nonorthosteric ligand-bound) receptor, they should indeed be independent of the orthosteric radioligand that is used (Lazareno and Birdsall, 1995). In addition, because our orthosteric radioligands labeled specific receptor states, our analysis indicates that under the current assay conditions, the binding of the allosteric modulators is not influence appreciably by the G protein coupling status of the receptor. The differences in the effects of each modulator on the binding of the orthosteric ligands could thus be adequately described and quantified by the estimated α values (Table 1), which were all greater than 1 when determined against the binding of [³H]CP 55,940 and less than 1 when determined against the binding of [³H]SR141716A. Cooperativity is known to be influenced by the nature of the ligand binding to the orthosteric site, and it is thus not surprising that the α values are different for each modulator as well as between each modulator and either an agonist or antagonist probe (May and Christopoulos, 2003).

It is noteworthy that dissociation kinetic studies using [³H]CP 55,940 as the probe also validated the allosteric nature of the Org compounds, because they all significantly decreased the dissociation rate constants for the radioligand. An alteration of the dissociation of a preformed orthosteric

ligand-receptor complex by a second ligand unambiguously demonstrates an allosteric interaction (Kostenis and Mohr, 1996). It is noteworthy that [^3H]CP 55,940 displayed biphasic dissociation kinetics, reflecting the presence of at least two receptor conformations (Devlin and Christopoulos, 2002). The rapidly dissociating component of [^3H]CP 55,940 binding probably represents binding to the low-affinity uncoupled receptors (R), whereas the slowly dissociating component possibly reflects binding to high-affinity activated (R^*) receptors. Irrespective of the actual nature of the receptor states detected in the dissociation assays, the Org compounds significantly decreased the dissociation rate constant for both the slow and fast components of agonist binding without significantly affecting the proportion of each state. The compounds therefore modulate the dissociation of [^3H]CP 55,940 from both the R and R^* receptor conformations. A reduction in the dissociation rate constant is in line with the positive cooperativity observed in the equilibrium binding assay of [^3H]CP 55,940. Together, these data suggest that the Org compounds bind allosterically to the CB_1 receptor and elicit a conformational change that increases agonist affinity for the orthosteric binding site.

Despite the positive allosteric enhancement of agonist binding observed in the radioligand binding assays, perhaps the most striking observation from our study was the dissimilitude between the effect on binding affinity and the effect

TABLE 4

Allosteric operational model binding parameters for various modulators at mouse vas deferens CB_1 receptors

All data sets (shown in Fig. 6) were globally analyzed using eq. 5 under *Materials and Methods*. The best-fit parameter values describing the activity of WIN 55,212 across the data sets were as follows: $\text{pK}_A = 6.86 \pm 0.28$; $\text{Log } \tau = 1.97 \pm 0.33$; $E_m = 82.7 \pm 3.6$; and $n = 0.86 \pm 0.18$. pK_B is the negative logarithm of the equilibrium dissociation constant for the allosteric modulator at the free receptor, determined using nonlinear regression according to eq. 2 under *Materials and Methods*. Values represent the mean \pm S.E. of four to eight experiments. $\text{Log } \alpha$ is the logarithm of the cooperativity factor. α is the antilogarithm (geometric mean) of the cooperativity factor, based on the estimated $\text{log } \alpha$ values. β is the empirical coupling constant, quantifying the fractional stimulus imparted by the modulator-occupied ternary complex.

Parameter	Allosteric Modulator		
	Org 27569	Org 27759	Org 29647
pK_B	7.57 ± 0.15	6.87 ± 0.28	7.46 ± 0.32
$\text{Log } \alpha$	1.20 ± 0.15	1.32 ± 0.27	1.35 ± 0.19
α	16 (11.2–22.4)	21 (11.2–38.9)	22 (14.4–34.7)
β	0.006 ± 0.002	0 ± 0.002	0.018 ± 0.007

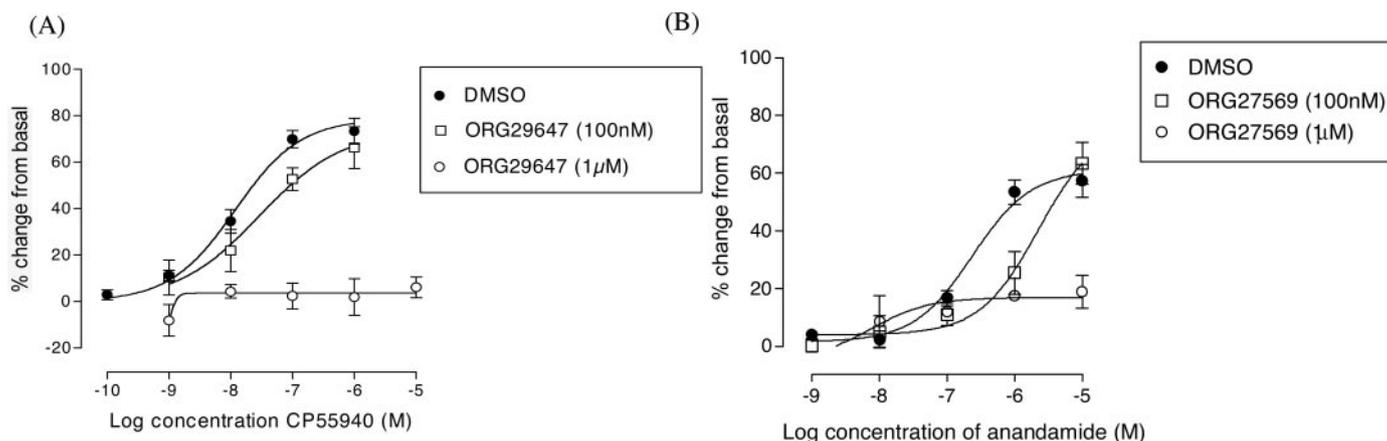

Fig. 7. Stimulation of binding of [^{35}S]GTP γ S to mouse brain membranes by CP 55,940 in the presence of vehicle (DMSO) or Org 29647 (A) and anandamide in the presence of vehicle (DMSO) or Org 27569 (B). Each symbol represents the mean percentage of stimulation above basal \pm S.E.M. ($n = 3\text{--}5$).

of the same modulators on agonist function (i.e., efficacy). In contrast to the binding assays, the Org compounds did not behave as allosteric enhancers but rather as insurmountable antagonists of receptor function; in the reporter gene assay, the [^{35}S]GTP γ S binding assay and the mouse vas deferens assay they elicited a significant reduction in the E_{max} value for CB_1 receptor agonists. The effects of the modulators on function were specifically manifested at the receptor when it was dually occupied by both orthosteric and allosteric ligand, because there was no evidence of agonist or inverse agonist properties of the modulators when tested alone (Fig. 5).

There are a number of examples in the recent literature of allosteric modulators that have profound inhibitory effects on orthosteric ligand efficacy but minimal effects on orthosteric ligand binding (Litschig et al., 1999; Zahnet et al., 2002; Watson et al., 2005), but our study is the first to reveal a striking difference between the magnitude and direction of allosteric modulation of orthosteric affinity, on the one hand, and efficacy, on the other. Numerous models have been proposed to specifically account for such behavior at the molecular level (Hall, 2000; Christopoulos and Kenakin, 2002; Parmentier et al., 2002). An essential feature of these models is that they contain multiple receptor states that are differentially stabilized by both orthosteric and allosteric ligands. As a consequence, the type of probe and the nature of the assay used can bias the detection of one set of receptor states over another and hence lead to a situation such as that described in our study where different observations are made depending on the experimental endpoint.

These findings have highly significant implications for drug discovery based on allosteric modulators, because they highlight the possibility of misclassification of novel ligands if they are not tested in as full a spectrum of biological assays as possible. In this regard, the operational model of allosterism, as presented in our study, can prove particularly useful. Like the molecular models described in the preceding paragraph, the operational model we have used is able to accommodate effects of allosteric modulators on both binding and function. However, the operational model has the additional advantage of containing fewer parameters than the molecular models; to our knowledge, this is the first application of such a model to derive quantitative functional parameter estimates for allosteric modulators (Table 4). The operational

model parameters K_A , K_B , and α have the same mechanistic meaning as they would in any molecular model of allosterism, and their determination can lead to useful information for structure-activity studies. Although the parameter β is used only as an empirical proportionality constant, its value can also provide useful insights. For example, β values significantly different to either 1 or 0 would be indicative of a ternary complex (ARB) species that retains the ability to signal in the presence of modulator, but in a modified way.

One point of divergence between the functional and the binding data concerns the apparent affinity of the modulators for the mouse CB₁ receptor; in the vas deferens bioassay, the estimated affinity of the Org compounds was higher than that estimated in the binding assay (Table 1 versus 4). At the

moment, the basis for this discrepancy between functional and binding affinity estimates remains unknown. However, a previous study by Pedder et al. (1991) revealed a striking divergence in the affinity estimates of the allosteric modulator, gallamine, at M₂ muscarinic receptors depending on the assay conditions used to determine this value. Indeed, differences in the affinity of the modulator spanned almost two orders of magnitude. It is also worth noting that these same variations in assay conditions had minimal effects on orthosteric ligand affinity estimates (Pedder et al., 1991). Because allosteric sites are, by their very nature, topographically distinct from the orthosteric site on a GPCR, they can be sensitive to ionic changes under conditions where orthosteric ligands are minimally affected. Such a scenario could explain

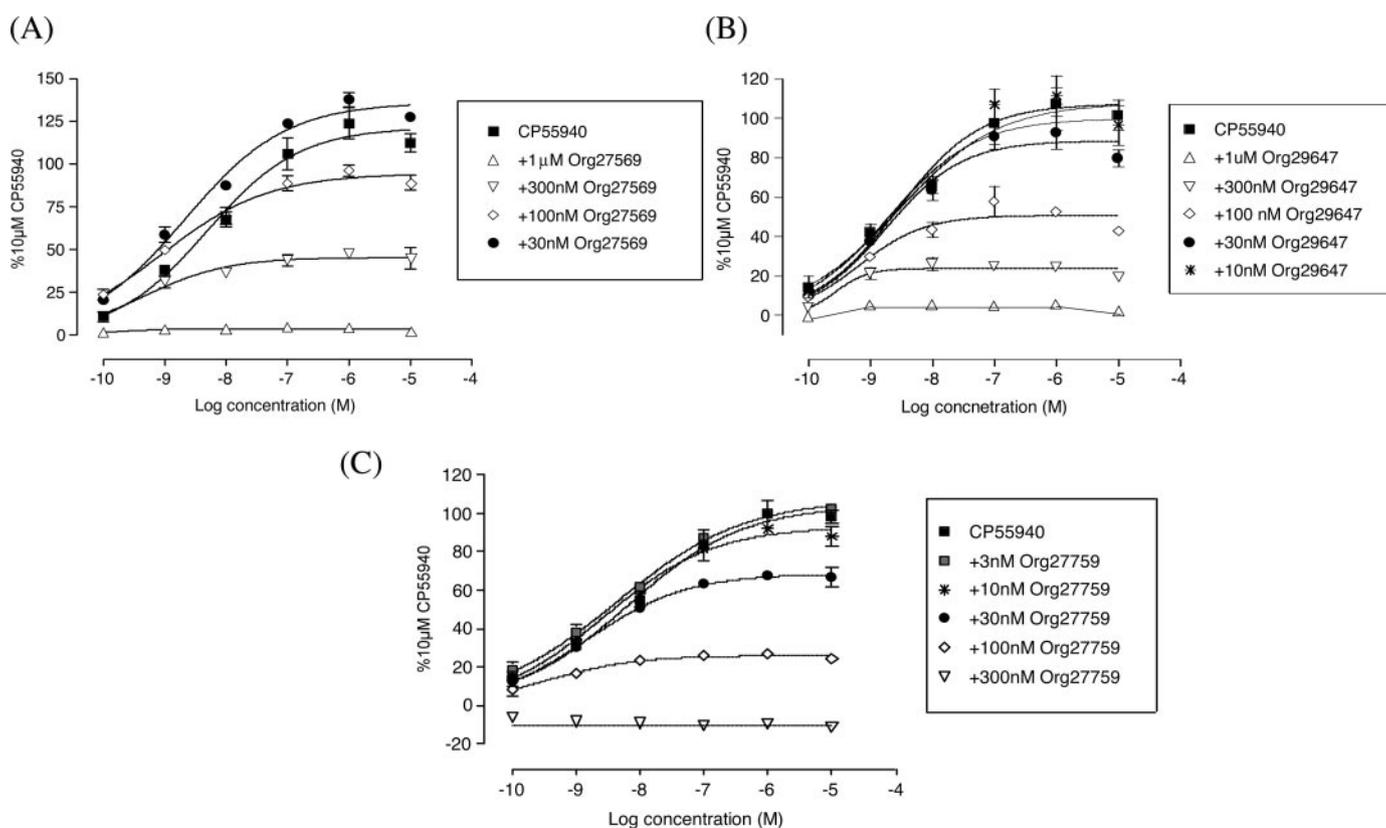

Fig. 8. Effect of Org compounds on enhancement of luciferase expression by CP 55,940 in Chinese hamster ovary cells that stably express the human cannabinoid CB₁ receptor that have been cotransfected with a luciferase reporter gene that is under the regulatory control of a AP1-response element. Each symbol represents the mean percentage of control stimulation (10 µM CP 55,940) ± S.E.M. ($n = 3$).

the discrepancy between the pK_B values obtained from our equilibrium binding (Table 1) and those obtained in the functional assay in the mouse *vas deferens* (Fig. 6). Together, our findings highlight the prospect of manipulating structure-activity to produce compounds that are either allosteric enhancers or allosteric antagonists of the CB₁ receptor. Endocannabinoid levels are significantly increased in models of inflammatory pain and CB₁ receptor agonists are highly effective analgesics in these models (Pertwee 2001; Iversen and Chapman, 2002; Rice et al., 2002). Furthermore, inhibitors of fatty acid amide hydrolase, the enzyme responsible for the rapid intracellular hydrolysis of anandamide, are antinociceptive in models of inflammatory pain. These compounds do not display the CNS side effects that are characteristic of direct CB₁ receptor agonism (Cravatt and Lichtman, 2004). Allosteric modulators of the cannabinoid CB₁ receptor would also offer the prospect of producing clinically useful compounds that do not display CNS side effects.

In conclusion, this investigation has provided the first evidence for an allosteric binding site on the cannabinoid CB₁ receptor. This site can be recognized by synthetic small molecules and offers the prospect of a new avenue of CB₁ receptor research that will complement the existing portfolio of selective direct agonists and competitive antagonists.

Appendix

An Operational Model of Allosteric Modulation

In the allosteric TCM (Fig. 1), the orthosteric ligand, A, is distributed over two receptor-bound species, AR and ARB. From this model, the concentration of the AR species in the presence of modulator, B, is as follows:

$$[AR] = \frac{[R]_T[A]}{[A]\left(1 + \frac{\alpha[B]}{K_B}\right) + K_A\left(1 + \frac{[B]}{K_B}\right)} \quad (6)$$

where $[R]_T$ denotes the total concentration of all receptor species (bound and unbound). Likewise, the concentration of the ARB ternary complex is described as:

$$[ARB] = \frac{[R]_T[A]}{[A](1 + K_B/\alpha[B]) + K_A\left(\frac{1}{\alpha} + K_B/\alpha[B]\right)} \quad (7)$$

In addition to effects on ligand binding affinity, allosteric modulators may also affect the efficacy of orthosteric agonists. To derive a functional model of allosterism that accounts for this possibility, it is first necessary to describe mathematically the effect of an allosteric modulator on the stimulus imparted by an orthosteric agonist to the cell, and the effect of stimulus-response coupling on the final observed response. In accordance with the conventions of classic receptor theory (Furchgott, 1966; Ehlert, 1988), the stimulus (S) is equal to the product of the concentration of orthosteric agonist-occupied receptors and the agonist intrinsic efficacy. In the presence of an allosteric modulator, the stimulus may thus be expressed as:

$$S = \epsilon[AR] + \epsilon\beta[ARB] \quad (8)$$

where ϵ denotes the intrinsic efficacy of the orthosteric ligand and β is a coupling factor that describes the ability of an

allosteric modulator to alter the signaling capacity of the [ARB] ternary complex. Values of $\beta < 1$ thus denote an attenuation in signaling, a situation that may be classed as a form of noncompetitive antagonism of functional responses, values of $\beta = 1$ denote no change in the signaling capacity of the receptor in the presence of modulator, and values of $\beta > 1$ denote an increased capacity of the receptor to signal in the presence of modulator. This model assumes that the allosteric modulator does not itself impart any stimulus to the receptor. Substitution of eqs. 6 and 7 into eq. 8, followed by simplification, results in the following general form of the allosteric stimulus equation:

$$S = \frac{\epsilon[R]_T[A](1 + \alpha\beta[B]/K_B)}{[A](1 + \alpha[B]/K_B) + K_A\left(1 + \frac{[B]}{K_B}\right)} \quad (9)$$

To derive the relationship between agonist concentration and final tissue response, an allowance must be made for stimulus-response coupling. Because most relationships between occupancy and response are nonlinear in nature, eq. 9 must be processed through a nonlinear function to derive an equation describing tissue response. One appropriate general function is the logistic equation, because it has been shown to closely model the shape of agonist concentration-response curves in many systems (Kenakin and Beek, 1982; Black and Leff, 1983). Thus, the tissue response (E), expressed as a fraction of the maximal response (E_m), may be described as a function of the stimulus as follows:

$$\frac{E}{E_m} = \frac{S^n}{K_S^n + S^n} \quad (10)$$

where the parameter K_S denotes a constant that governs the efficiency of stimulus-response coupling, and n denotes a logistic slope factor. Substituting eq. 9 into eq. 10, and defining $\tau = \epsilon[R]_T/K_S$ as an operational measure of efficacy, gives the following operational model of agonism in the presence of an allosteric modulator:

$$E = \frac{E_m \tau^n [A]^n \left(1 + \frac{\alpha\beta[B]}{K_B}\right)^n}{\left[[A] \left(1 + \frac{\alpha[B]}{K_B}\right) + K_A \left(1 + \frac{[B]}{K_B}\right) \right]^n + \tau^n [A]^n \left(1 + \frac{\alpha\beta[B]}{K_B}\right)^n} \quad (11)$$
