The effects of cannabinoid administration on sleep: a systematic review of human studies

Peter J. Gates*, Lucy Albertella, Jan Copeland
National Cannabis Prevention and Information Centre, UNSW Medicine, Australia

SUMMARY
This paper reviews the literature regarding the effects of cannabinoid administration on sleep in humans. A literature search using a set of cannabinoid and sleep-related terms was conducted across eight electronic databases. Human studies that involved the administration of cannabinoids and at least one quantitative sleep-related measure were included. Review papers, opinion pieces, letters or editorials, case studies (final N < 7), published abstracts, posters, and non-English papers were excluded. Thirty-nine publications were included in the review. Findings were mixed and showed various effects of cannabinoid administration on several aspects of sleep. Methodological issues in the majority of studies to date, however, preclude any definitive conclusion.

Introduction
Cannabis is the most frequently used illicit drug around the globe and is estimated to be used by approximately 4.5% of the world’s population—a prevalence which is currently increasing [1]. Cannabis use is especially prevalent among younger age groups compared to older age groups who may instead begin to embrace new roles and responsibilities [2]. This pattern of use is especially concerning as it is well established that early onset to cannabis use and frequent use are significant predictors of a range of health problems including mental health concerns [3] and reduced educational outcomes [4], as well as respiratory complaints [5] and cannabis use disorder [6]. In contrast, through the isolation of the two main active components of cannabis—the ‘cannabinoids’ tetrahydrocannabinol (THC) and cannabidiol (CBD) among at least 60 others [7]—cannabis-based medicines (CBM) have been developed which have been used to treat a range of health problems, most notably those involving pain and muscle spasm [8].

As with any psychoactive substance there are many different motivations to use cannabis, however, it is typically used for enjoyment or fun and for promoting social cohesion [9]. A less well understood motive is use to assist with sleep problems. This motive is not uncommon and has been reported by one quarter of a large sample of cannabis using high school graduates [9]. Indeed, intoxication from cannabis use is most commonly described to involve a feeling of relaxation [10]. Interestingly, there have been few studies specifically focussed on the relationship between cannabis use and sleep. This may be surprising given the health importance of sleep. That is, insomnia, the most common sleep disorder [11], is a known risk factor for multiple impairments across quality of life domains (most notably depression and anxiety) [12], which ultimately leads to an increase in the utilisation of health care resources amongst sufferers [13].

Early investigations of cannabis use and sleep gained momentum in the 1970s. Many of these studies used objective measures (polysomnograph technology) to investigate sleep and have been reviewed by Schierenbeck and colleagues [14]. These authors noted that a reduction to rapid eye movement (REM) sleep and REM density was the most consistent finding, however; their interpretation of findings was not considered reliable due to the small sample sizes of the studies reviewed. More recent understanding has come from medicinal cannabis use trials which include a secondary measure of sleep as a gauge of positive treatment outcomes (with a primary measure relating specifically to the illness under study). A subsection of these trials involving clinical studies of Sativex (a THC and CBD based oral spray) have recently been reviewed by Russo and colleagues [15]. These authors concluded that the use of Sativex for the treatment of spasticity and
pain was likely to improve subjective sleep parameters but was unlikely to result in a significant change in sleep architecture.

Unfortunately, the current understanding of the effects of cannabis use on sleep is clouded by mixed findings between studies that typically lack statistical control for confounding factors. Notably, medicinal cannabis use has recently been described to alleviate sleep problems by medicinal users [16–18], while cannabis use is a reported risk factor for sleep problems in the community [19–22]. Moreover, sleeping problems are among the most commonly experienced withdrawal symptoms when abstaining from cannabis use [23,24]. Despite this, research designed to develop a better understanding of the effects of cannabis use on sleep in humans is rarely conducted.

Recognising the effects of cannabis use on sleep is important for both the cannabis user and for health providers tasked with assisting behavioural change. If demonstrated to be harmful, this knowledge may act as a motivational tool for those deciding whether or not to use cannabis. In addition, such evidence may assist clinicians to reduce the risk of relapse to cannabis use among their clients by assessing and addressing sleep problems as necessary. In order to clarify the effects of cannabis on sleep, we conducted a systematic review of all papers which included human participants and an assessment of sleep following the administration of a measured cannabis dose. Unlike previous reviews, we include: 1) studies that used either objective or subjective measures of sleep; 2) studies that involved the administration of any cannabinoid or CBM; and 3) an assessment of the risk of bias present in each study. As participants in those trials of CBM suffered from illnesses that likely impact on their sleep, the associated articles are presented separately to isolate possible attribution bias.

Method

Literature search

English language studies on human participants were located through online search of eight electronic databases (Embase, CINAHL, Cochrane Library/EBM Reviews, Medline, and PsyCINFO for published studies and Project Cork, DRUG, and PsyEXTRA for grey literature). The search strategy included the keywords “cannabinoid/s, or, tetrahydrocannabinol, or THC, or cannabis/marijuana” and “sleep, or sleep onset, or sleep apnea, or sleep treatment, or sleep wake cycle, or sleep deprivation, or rapid eye movement (REM) sleep, or non-rapid eye movement (NREM) sleep, or sleep disorder, or insomnia”. In addition we attempted to contact primary investigators who had conducted studies including measures of both cannabis and sleep but did not describe the two in the results of their manuscript. Review papers, posters, qualitative articles, opinion pieces, letters or editorials, case reports (final N < 7), and published abstracts were excluded. For purposes of this review, only those papers involving the administration of cannabinooids or CBM were included while papers describing the prevalence of sleep problems among cannabis users or those on associations between use and sleep (41 studies), and papers describing cannabis withdrawal (44 studies) were excluded. This review included all papers current to the end of 2012 and did not exclude studies on the basis of methodological flaws.

Initial searching resulted in 2215 manuscripts being identified, which were independently reviewed by two research staff (PC and LA) in order to remove duplicates and articles meeting exclusion criteria. A consensus was reached and a total of 730 duplicates and 1446 articles meeting exclusion criteria were removed, leaving 39 relevant articles. These articles were either: 1) studies involving the administration of cannabis to recreational cannabis users or cannabis naïve individuals which included a measure of its effect on sleep (11 articles), or 2) clinical trials involving medicinal cannabis use for a health condition which included a measure of its effect on sleep (28 articles).

Article quality

In order to assess the risk of bias in each article, a custom assessment of article quality and risk of bias was purpose built following suggestions from the Cochrane Collaboration’s Risk of Bias Assessment Tool [25], the Effective Practice and Organisation of Care Review Group Data Collection Checklist [26] and the assessments of risk of bias by Viswanathan and colleagues [27]. A ratio (reported as a percentage) was calculated to represent which of 38 different factors that the article had adequately addressed compared to the number left unaddressed. As such, a score of 100% was awarded when the article addressed all appropriate risks of bias adequately, while 50% was awarded when the article addressed an equal number of risks of bias compared to those left unaddressed.

Results

Non-medical cannabis use and sleep

A total of 11 studies investigated the impact of recreational cannabis use on sleep with a collective sample size of 203 participants (see Table 1). The overall quality of these studies was poor (range: 17-84%, average: 42.6%), meaning that a substantial risk of bias was introduced across the literature. This risk was most commonly due to a lack of control for confounding factors such as pre-existing sleep problems or participant gender and age. This is significant as the prevalence of insomnia increases with age and is greater among females [11]. Further, it is noteworthy that no study was conducted outside of the US and Canada. Moreover, meaningful comparisons between studies were limited as the employed measure of sleep and the cannabis dose and dosing duration all varied substantially. A total of six studies employed objective measures of sleep [electroencephalogram (EEG)] [28–33], although only one of these studies was conducted within the past decade [31]. These studies are summarised separately from the remaining studies which employed subjective measures of sleep.

There was little consistency in the results of the six studies with objective sleep measures. That is, slow wave sleep was described to increase in one study [28] (although decreased by the eighth day of withdrawal), three studies reported a decrease [31–33], and one study showed no change [30]. REM sleep was reported to

increase in one study [30], decrease in a second study [33], while four studies showed no effect [28,29,31,32]. Stage two sleep was reported to increase in two studies [28,33], while four studies showed no effect [29–32]. Sleep latency was reported to increase in one study [30], decrease on a high THC dose in a second study [31], while two studies showed no effect [28,32] and two studies did not measure sleep latency [29,33]. A single study reported cessation of body movement during sleep following a single dose [33], while another study showed an initial decrease throughout the first week of dosing followed by an increase in the number of movements [28], while four studies did not report on body movements [29–32]. In contrast, cannabis was not reported to significantly impact on overall sleep time or time spent in stage one sleep.

The most recent study was conducted in 2004 and was of the highest quality (84.4%) [31]. This study recruited four male and four female occasional cannabis users into a double-blind, placebo-controlled, crossover trial. Each participant received a single dose (administered using oral sprays one week apart) of 15 mg THC extract, 5 mg THC with 5 mg CBD extract, 15 mg THC with 15 mg CBD extract, placebo at 22:00 h, 30 min before ‘lights out’. Other substance use (including caffeine) was kept to a minimum, although two participants were regular tobacco smokers. This study not only objectively investigated sleep using EEG immediately following drug administration, but also included a subjective measure of morning after sleepiness. The study found that the effects of 15 mg THC without the concomitant administration of CBD produced no statistically significant effects on sleep compared to placebo with the exception that morning after sleepiness increased significantly. In contrast, time spent in stage three sleep decreased, and duration of wakefulness increased significantly compared to the placebo for the 15 mg THC + CBD dose only (not the 5 mg dose). No significant morning after effect was observed for the 5 mg THC + CBD dose, however; the 15 mg THC + CBD dose was associated with significantly increased sleepiness. The authors summarised that “THC would appear to be a sedative compound, whereas CBD would appear to have some alerting properties” (31) p310. In addition to the very small sample size (and resulting lack of statistical power) there were two main limitations to this study that should be considered. First, although the authors described the study to be double-blind, the fidelity of blinding methods were not confirmed in the study results. Second, the experimental procedures used allowed for the objective measurement of sleep on one night following administration of a single dose of cannabis and thus excluded investigation of longer term use.

A total of five studies [34–38] employed subjective measures of sleep, most commonly the Pittsburgh sleep quality index [39]. Across these studies, the most consistently reported impact of administering cannabis on sleep was a decrease to sleep latency (decreased in three studies [35,36,38], no effect shown in one study [37], and not measured in one study [34]). In contrast, no study reported a significant effect on number of night time sleep awakenings (investigated in four studies [35–38]) or daytime behaviour upon waking (investigated in three studies [35–37]) and there were mixed results regarding overall sleep time (in one study heavy cannabis users slept longer than moderate users on days following consumption and all cannabis users slept longer than alcohol-only users [34], however, no effect was reported in a second study [38]) and measures of sleep quality or satisfaction (increased in one study [35], while two studies did not find an effect [36,37] and two studies did not include this measure [34,38]).

A total of three studies included varying cannabis doses [34,37,38]. The majority of these studies reported no effect of dose (using subjective measures). That is, higher doses improved sleep in one study [34], while two studies showed no effect of dose [37,38].

Rog et al. 2005  [54]  UK  Flexible oral spray dose of Sativex (up to 48 doses daily, each 2.7 mg/2.5 mg THC/CBD) for five weeks or placebo  Compared to placebo (unconfirmed blinding)  Numerical rating on “pain related sleep disturbance”  MS severity ratings, medications, age, gender  21.25% male, aged 40-42 (8.1) y, all suffering MS (n = 66)/64  Pain related sleep disturbance (dose effect was unclear)

Novotna et al. 2011  [53]  Multi-national  Mean of 8.3 oral spray doses of Sativex (each 2.7mg/2.5mg THC/CBD) for 16 wk or placebo  Compared to placebo (unconfirmed blinding)  Numerical rating on “sleep quality”  Substance abuse, MS severity ratings, medications, psychiatric disorder, age, gender, BMI  209 male, aged 48.6 (9.3) y, 100% Caucasian, all suffering MS (n = 241)/224  Sleep quality (dose effect was unclear)

Nurmikko et al. 2007  [42]  Multi-national  An average of 10.9 (6.8) doses of Sativex oral spray per day (each dose was 2.7 mg THC/2.5 mg CBD) over five weeks  Compared with placebo (no blinding)  Numerical rating on ‘sleep disturbance’  Pain medication, physical and mental health  40.85% male, aged 53.4 (9.7) y, all suffering pain (n = 163)/103  Sleep disturbance (dose effect was clear)

Portenoy et al. 2012  [41]  Multi-national  Two-16 oral spray doses per day of Sativex on a graduating dose plan (5.4 – 43.2 mg THC and 5 – 40 mg CBD over nine weeks)  Compared with placebo (unconfirmed double blind)  Numerical rating on sleep disruption  Gender, ethnicity, cannabis use, medications, physical health  51.7% male, aged 58.0 (12.2) y, 77.25% Caucasian, all suffering pain (n = 360)/261  Sleep disruption (on low dose only (one to four doses per day)

Vane et al. 2004  [55]  Germany  Graduating dose of oral spray sativex up to 12 doses (each 2.5 mg/1.9 mg THC/ CBD) over four weeks or placebo  Compared to placebo (unconfirmed blinding)  Diary recordings on “falling asleep fast” and “waking up again”  Age, gender, substance use, MS severity ratings  49.15% male, aged 54.9 (10.0) y, all suffering MS (n = 57)/37  No effect on indicators of sleep latency or sleep quality were found

Wade et al. 2004  [56]  UK  Graduating dose of oral spray sativex up to 48 doses daily – typically 15 doses (each 2.7 mg/2.5 mg THC/CBD) for six weeks  Compared to placebo (unconfirmed blinding)  Visual analogue scale on sleep quality, time asleep, and “feeling upon waking”  Age, gender, substance abuse, MS severity ratings  38.15% male, typically aged over 50 y, all suffering MS (n = 160)/154  Sleep disturbance (dose effect was unclear)

Other cannabis-based medicines

Gross et al. 1983  [82]  US  Graduating doses of THC capsules increasing from 2.5 mg to 10 mg, three times per day over four weeks then graduating dose of Diazepam (0 – 15 mg three times three times over four weeks  Compared to diazepam (unconfirmed blinding)  Hopkins symptom checklist-90 (one unclear item on sleep disturbance)  Age, substance use, weight, significant health concerns  0% male, aged 23.6 (1.6) y, 100% Caucasian, all suffering primary anorexia nervosa (n = 118)  Sleep disturbance (dose effect was unclear)

Haroutunian et al. 2008  [49]  Israel  Oral dose of THC (5 mg) two to three times daily for the period of the participant’s “ongoing anergic drug regimen”  Unclear impact rating only (no blinding)  Numerical rating on “sleeping better”  None  53.8% male, aged 46 (17) y, all suffering pain (n = 13)/13  Impact of THC on ‘sleeping better’ was rated as an average of 3.1 out of 10

Notcutt et al. 2004  [50]  UK  Oral spray dose of THC and CBD alone, or THC combined with CBD (all 2.5 mg), and placebo – all taken two to eight times daily in a randomised order for two weeks (12 experimental weeks total)  Compared to placebo (unconfirmed double blind)  Number of hours slept and percentage of nights with “good quality sleep”  Mental health, pain ratings, previous cannabis use  29% male, aged 42.5 y on average, all suffering pain (n = 34)/31  Percentage of “good” nights favoured THC with CBD (55.4%), over THC (42.8%), CBD (36.9%), and placebo (17%). No effect on time asleep (dose effect was unclear)

ALS = amyotrophic lateral sclerosis; BMI = body mass index; CBD = cannabidiol; MS = multiple sclerosis; PTSD = post-traumatic stress disorder; 51–54 = stages one to four sleep time; THC = delta-9-tetrahydrocannabinol.

* For each article the participants’ gender breakdown, age in years (expressed as the mean [standard deviation] when given), history of cannabis use, ethnicity, and other relevant demographic variables are provided subject to the detail published in the associated article.
Medicinal cannabis use and sleep (28 studies; combined N = 3658)

A total of 28 medicinal cannabis use studies included a measure of sleep as a treatment outcome for various illnesses with a collective sample size of 3658 participants (see Table 2 for an overview). Ailments under investigation included pain (12 studies [40–51]), multiple sclerosis (nine studies [52–60]), and other conditions such as anorexia, cancer, and immune deficiency (seven studies [61–67]). The studies were of synthetic analogues of THC including marinol or dronabinol and nabilone (14 studies [40,43,44,46,48,49,51,57,61,62,64–67]); synthetic analogues of CBD (Canndor; Institute for Clinical Research, IKF, Berlin, Germany) (four studies [50,57,59,60]); or cannabis extracts with a similar ratio of THC to CBD; referred to as nabiximols (Sativex; GW Pharma Ltd., Wiltshire, UK) (14 studies [41,42,45,47,50,52–56,58–60,63]). The THC analogue capsules have shown promise for the treatment of cancer-related nausea and vomiting, and for anorexia associated with weight loss in patients with acquired immune deficiency syndrome [8]. In turn, the CBD analogue capsules have shown anxiolytic and antipsychotic like actions [7]. Finally, the nabiximols oromucosal spray has shown particular promise for treating peripheral neuropathic cancer and spasticity related pain [15].

The quality of these CBM trials with measures of sleep was poor. Scores ranged from 17% to 69%, with an average score of 48.6%. Across studies, the low quality scores were commonly a result of non-validated measures of sleep (typically simple numerical ratings) and a lack of confirmation that participants were adequately blinded to the dose of cannabis used (particularly among nabilone and dronabinol trials while blinding adequacy is more likely in sativex/nabiximol trials [68]). Although the majority of studies did not include a validated measure of sleep, most studies reported a significant and positive impact on sleep in the clinical trial. That is, 20 studies showed an improvement to sleep [40–43,45–47,50,51,53,54,56–60,62,64–67], although this improvement was no longer significant at the end of the experiment in two studies [58,64] while one study did not report on sleep per se but showed a lessening of bad dreams [66]. Research regarding whether cannabis-based medicines are more beneficial to sleep than alternative experimental drugs was mixed. Two studies supported the sleep enhancing effects of CBM over diazepam (when treating primary anorexia nervosa) [62] and amitriptyline (treating insomnia among patients with fibromyalgia) [67]; however, three studies did not support CBM over ketoprofen (when treating pain and nausea) [44], gabapentin [46] or dihydrocodeine (both treating neuropathic pain) [48]. Finally, six studies did not find a significant association between medicinal cannabis use and sleep [44,48,52,55,61,63] and one article (quality rating of 17.2%) referred only to the impact of THC on sleep and this was rated as 3.1 out of 10 (anchor-point descriptions were not provided) [49].

A total of seven studies included a validated subjective measure of sleep [40,43,46,51,61,65,67]—most commonly Medical Outcomes Study sleep scale [69] or the Leeds sleep evaluation questionnaire [70]. The results from these seven studies were varied. In summary, four studies reported on sleep disturbance/problems: each showed a reduction [40,46,65,67] although this reduction was no greater than reductions associated with an alternative active drug [46] and one study showed a reduction only on high dose [65]. Three studies reported on sleep quality: two showed an increase [40,65] while one reported no effect [43]. Two studies reported on sleep latency: one study reported an improvement although on high cannabis dose only [43], while the other showed no effect [67]. Two studies reported on sleep restfulness: both showed a positive effect [43,67]. Two studies reported on an overall index score: one study showed significant improvement [51] and the other no effect [61]. In contrast, two studies reported on night time awakenings and neither showed an effect [43,67].

In addition, two notable studies included an objective measure of sleep [64,65]. The first included controls for substance use and health problems and reported only on total sleep time [65]. This study showed no effect by objective measure, however; a significant effect was seen by subjective measure on high dose (10 mg THC, four times daily for four days) [65]. The second study included similar controls but utilised a greater dose of THC (increasing dose of 20–40 mg administered four times daily for 16 d) [64]. In this study, a significantly greater period of NREM sleep was reported across the first eight days only, along with fewer night time awakenings, and a higher quality sleep compared to baseline.

Finally, three studies included an analysis on the effect of dose [41,43,65], two of which included validated measures of sleep [43,65]. These two studies each reported that the high dose of cannabis (3.9% and 9.4% THC) outperformed the low dose (2% and 2.5–6% THC, respectively). The third study (without a validated measure of sleep) reported that the low dose (1–4 doses of 5.4 mg/5 mg THC/CBD) outperformed the high dose (5–16 doses) [41].

Conclusions

We have reviewed 39 manuscripts that involved the administration of cannabis and included a quantitative measure of sleep. Overwhelmingly these articles described studies that carried a substantial risk of bias, typically by failing to control for other substance use, using measures without psychometric validation and, in the case of many clinical trials, failing to blind participants. As such, conclusions from this review are tentative due to existing studies suffering a number of methodological issues and findings being largely mixed. That said, the evidence indicates that following cannabis use there may be a decrease in slow wave sleep (SWS) times and a corresponding increase in time spent in stage 2 sleep. There does not appear to be a consistent effect on total sleep time. Among those with a medical condition that impacts upon sleep, reductions in sleep disturbance (not necessarily causing early awakening) appear to improve quality of sleep without impacting on total sleep time. Although there appears to be a small dose effect, without further study the impact of varying doses of cannabis is less clear.

These results are consistent with one interpretation that cannabis is typically not beneficial to sleep except among medicinal cannabis users who are identified by the presence of pre-existing sleep interrupting symptoms such as pain. As such, cannabis may be thought to improve sleep via the mediating improvement of these confounding symptoms. In particular, this interpretation of results is supported by the two studies that included a measure of pain-related sleep problems [43,46] and an additional study which showed that only those participants reporting a reduction in spasticity showed improved sleep [52]. In addition, CBM and natural cannabis are categorically different beyond the fact that medicinal cannabis is typically taken orally. That is, each consists of varying levels of cannabinoids, particularly the ratio of THC to CBD, which may contribute to differences in sleep-related outcomes [31]. Indeed, nabiximols contain a roughly equal THC:CBD ratio, while natural cannabis is very low in CBD [71], limiting the generalisation between the two.

The results of the reviewed studies, although mixed, indicate that cannabis may have an effect on various aspects of sleep, including sleep architecture and subjective sleep quality. Given the risk of bias associated with the reviewed studies, there is a clear need for a large scale, longitudinal and well controlled study on the
specific effects of cannabinoids on sleep. The health impact of these effects is also unclear and is a necessary topic for future research among samples of cannabis users.

Practice points
Cannabinoid use among recreational users:
1) may interrupt the normal cycles of sleep — particularly SWS sleep; and
2) does not appear to consistently cause any significant change to the time spent asleep or the number of night time awakenings, but may leave an impression of non-restful sleep.

Cannabinoid use among users with a medical condition known to disturb sleep:
1) shows some consistency across studies of improved sleep via reduced night time disturbances, although the majority of these studies do not include psychometrically validated measures; and
2) shows relatively inconsistent effects on sleep among studies with objective measures.

Research agenda
To better clarify the impact of cannabinoid use on sleep further study is required that:
1) is longitudinal to assess the impact of tolerance;
2) includes both an objective and validated subjective measure of sleep and sleep-related health outcomes to assess any changes to sleep and how these changes are experienced;
3) includes varying doses of cannabinoids to assess the impact of frequency and intensity of use; and
4) includes controls for confounding variables such as age, gender and substance use history.
